Selective visual attention involves dynamic interplay between attentional control systems and sensory brain structures. We used event-related functional magnetic resonance imaging (fMRI) during a cued spatial-attention task to dissociate brain activity related to attentional control from that related to selective processing of target stimuli. Distinct networks were engaged by attention-directing cues versus subsequent targets. Superior frontal, inferior parietal and superior temporal cortex were selectively activated by cues, indicating that these structures are part of a network for voluntary attentional control. This control biased activity in multiple visual cortical areas, resulting in selective sensory processing of relevant visual targets.

Selective attention enables us to focus awareness on objects and events that are relevant to our immediate goals. Spatial attention, the selective direction of visual attention toward a location, can occur covertly, without overt movements of the head or eyes. Theoretically, mechanisms of covert, voluntary spatial attention can be decomposed into elementary mental operations: disengaging attention from the current focus, orienting attention to a new locus and selectively modulating new stimulus inputs are three stages proposed in current models^{1,2}. Attentional disengagement and voluntary orienting can be considered aspects of top-down attentional control, whereas subsequent selective modulation of sensory inputs reflects the result of this top-down control on sensory information processing.

Studies in neurological patients and physiological studies in humans and animals implicate a network of cortical and subcortical regions that support visual selective attention^{3–6}. Neuroimaging studies identify areas involved in spatial attention in the frontal, parietal, temporal and occipital lobes as well as in subcortical structures^{7–11}. However, although neuroimaging studies implicate various brain regions in selective attention, inherent limitations of classical neuroimaging analysis impair efforts to relate neural structures/networks to specific attentional operations. Specifically, such methodologies use averaging of hemodynamic responses over seconds or minutes, a time course that is too long to permit direct viewing of brain activity related to the subcomponents of task performance. As a result, human neuroimaging studies to date are only partly successful in distinguishing between neural activity related to top-down attentional-control processes and activity related to selective sensory and motor processing.

Recordings of event-related neuroelectric potentials (ERPs) allow the selective averaging of responses to different classes of events and, thus, serve to index mechanisms of attentional control separately from selective stimulus processing during spatial attention¹². However, although ERPs provide information about the timing of neural processes, the limited spatial resolution of this approach hinders identification of the neural structures involved in attentional control. Advances in functional magnetic resonance imaging (fMRI)

analysis^{13,14} allowed us to combine the spatial resolution necessary for localization of neural activity, which this technique provides, with neuroimaging methods that selectively extract components of hemodynamic activity¹⁵ correlated with distinct aspects of complex-task performance.

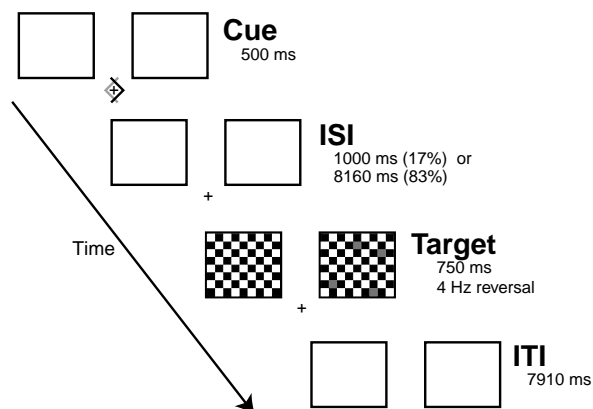

Here we used event-related fMRI methods to determine which brain regions were involved in attentional-control processes and to distinguish these from areas involved in subsequent selective processing of target stimuli. This was accomplished by separately convolving the onsets of the cue and target stimuli with synthetic hemodynamic response functions. Subjects oriented attention covertly (without moving their eyes) to spatial locations based on instructive cues shown at fixation (Fig. 1). Subsequently, reversing checkerboard stimuli were presented at both sides of the visual field, and subjects were required to discriminate whether the checkerboard at the cued location contained some gray checks or only black and white checks and to respond accordingly. All stimuli in the opposite (uncued) hemifield were to be ignored.

Based on previous studies implicating various brain regions in attentional control^{5,7,8,11}, we hypothesized that attentional-control processes in response to an instructive cue directing spatial attention would activate a network of regions in frontal and parietal cortex. Additionally, based on ERP studies in humans¹², regions of occipital cortex corresponding to portions of visual space indicated by the cue should show spatially specific changes in activity in anticipation of selective processing of target stimuli. We also expected lateralized changes in activity of occipitotemporal regions in response to the bilateral target stimuli to reflect spatial attention^{7–11}. In line with these predictions, we found distinct patterns of neural activation for attention-directing cues as compared with those for subsequent target stimuli, thereby distinguishing top-down attentional control from selective modulations of target processing in sensory structures.

RESULTS

Subjects discriminated black and white checkerboards from those containing some gray checks at the cued location with a mean

Fig. 1. Stimuli and timing. For simplicity, we show here the inverse black/white contrast of the actual stimulus screen; subjects saw a black background with white outline boxes and fixation cross, and the cues were overlapping isoluminant yellow and blue arrows (pointing in opposite directions). Subjects were told which color arrow to attend for the entire session and were required to covertly orient their attention to the visual field location indicated by that arrow. After a variable interstimulus interval (1000 or 8160 ms), the target checkerboards appeared bilaterally, and subjects were required to perform a discrimination of the checkerboard stimuli at the attended location only.

accuracy of 83.9% correct responses. This corresponded to a mean d' score of 2.99.

We investigated circuitry involved in attentional control by identifying regions activated in response to the cue. Multiple cortical areas were activated following cue presentation, but before target presentation (Fig. 2; Table 1). These regions were activated regardless of the cue direction: brain regions activated by rightward- and leftward-pointing cues were highly similar (with the exception of the extrastriate cortex; see below). Regions of the inferior parietal lobule (in the lateral intraparietal sulcus, or IPS), the superior parietal lobule (SPL) and the posterior cingulate cortex (PC) in both hemispheres were activated in response to the instructive cues. Regions of the lateral and medial superior frontal lobes, including the frontal eye fields (FEF), were also activated bilaterally. These

frontal activations tended to be larger in the left hemisphere, regardless of cue direction. In addition, cue stimuli generated activity along the superior temporal sulcus (STS). With the exception of the superior parietal lobule, none of these regions were activated in separate sensory control scans in which cues were viewed passively or were irrelevant to the task (and, therefore, did not instruct the subjects to direct attention to a single location). Posterior occipital regions of cortex were activated in response to the cues, but these regions were also activated by cues in the sensory-control scans, indicating that they represented simple sensory processing of the cues. Additionally, the cues produced bilateral activations in the region of the insula near the putamen.

In contrast, the target stimuli evoked neural activity in brain areas that were largely distinct from those activated by the attention-directing cues (Fig. 3; Table 2). Bilateral activations in the supplementary motor area (SMA) extending into regions of the midcingulate gyrus and activations surrounding the central sulcus were found in response to targets whether attention was directed to the right or left. Ventrolateral prefrontal areas were also bilaterally activated by the targets. None of these regions were activated by the cues. Only the superior parietal lobule was found to

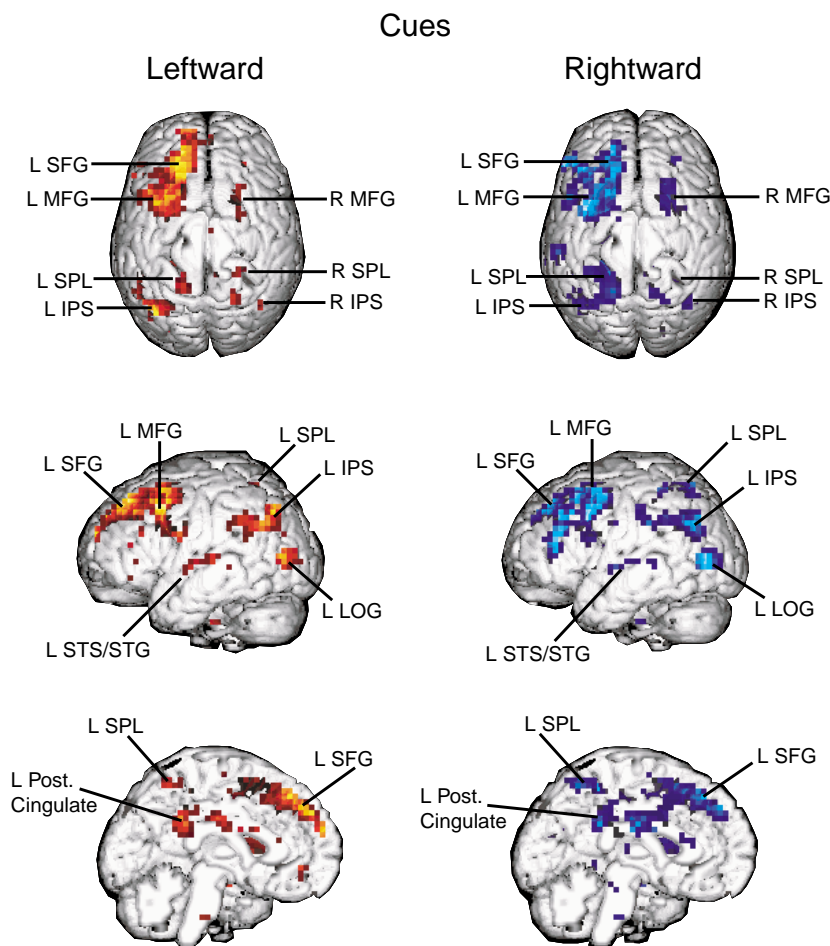

Fig. 2. Activity related to attentional control. Data for brain regions significantly activated in response to the cue stimuli were overlaid onto a brain rendered in 3D. Left column, activations to cues instructing subjects to orient attention to the left visual field location. Right column, activations to cues instructing subjects to attend the right visual field location. Top panels, dorsal view of the brain (frontal pole at top); middle and bottom panels, lateral and medial views, respectively, of the left hemisphere. Labels indicate the brain regions referred to in Table 1. The Z-values and stereotactic coordinates for the regional maxima are given in Table 1. be activated in response to both targets and cues. Additionally, bilateral targets activated several regions of the ventral and dorsal occipital cortex of both hemispheres. Cue and target responses were directly statistically compared (Tables 1 and 2; Fig. 4).

To investigate the consequences of lateralized spatial attention on stimulus processing, the event-related neural activity evoked by the bilateral target stimuli was evaluated for attention to the left versus right. In line with previous neuroimaging studies in humans^{9,10,16–19} and related findings in animals³, attending to the left visual field increased activity in the right ventral occipital cortex, whereas attending to the right increased activity in the left occipital cortex (Fig. 5a). In addition, activity in a more dorsal region of visual cortex was also modulated by spatial attention.

To relate these attention-related activations to specific visual-field areas, the vertical and horizontal meridian were mapped in two subjects to identify the borders of the early cortical visual areas^{20,21}. Although the spatial smoothing used in the present analysis tended to blend together the attention-related activations in adjacent visual cortical areas, the contralateral attention-related activations in occipital cortex can be seen to cross multiple visual area borders from V2 through V4 (Fig. 5b), an observation in line with other reports^{10,18,22}.

Models of spatial attention propose that attention effects on target processing result from a gain-control mechanism that enhances the excitability of extrastriate neurons coding attended regions of visual space^{4,9,23}. To investigate this possibility, we further examined extrastriate cortex for evidence of spatially

selective attentional activations in response to the direction of the instructive cue, but before target presentation, using the attention-related activations to targets as regions of interest. Direct statistical evaluation of the cue-left versus cue-right effects revealed relative increases of activity in extrastriate cortex contralateral to the direction of attention. These contralateral cue-related activations overlapped closely with the extrastriate regions showing attentional modulations in response to the subsequent targets (Fig. 6). That is, there was a relative increase in activity in the visual cortical regions representing the spatial locations of the expected target stimuli before the target stimuli were actually presented. These differential activations were not related to inherent sensory features of the cues that activated separate cortical regions in control sessions.

DISCUSSION

This study used event-related fMRI methods to distinguish between neural networks involved in top-down attentional-control processes and those participating in the subsequent spatially selective attentional processing of target stimuli. A network of cortical areas including superior frontal, inferior parietal and superior temporal brain regions were implicated in top-down attentional control because they were found to be active only in response to instructive cues. In contrast, other regions of the cortex, including the ventrolateral prefrontal cortex, anterior cingulate and supplementary motor area, were found to be selectively activated by the target stimuli, suggesting that these

areas may be more involved in selective stimulus processing and/or response mechanisms.

The activation in the inferior parietal lobule (specifically, IPS) in response to the cues, but not targets, suggests that this region of parietal cortex is involved in attentional-control processes. This finding supports prior evidence from blocked-design imaging studies, which inferred the role of inferior parietal cortex based on activity averaged across blocks of trials^{8,11,24,25}, as well as work in animals²⁶, but provides the first direct evidence that these regions of the inferior parietal lobule are specifically linked to attentional control in humans. The present findings in inferior parietal cortex suggest a role for this brain region in attentional control mechanisms, which may include shifting attention^{7,24}, or working memory processes engaged to support task performance²⁷.

In contrast, regions in superior parietal cortex, also proposed to be involved in attentional orienting⁷, were not only activated by the cue stimuli, but were also (and to a greater extent) activated in response to the target stimuli. This finding agrees with neuroimaging studies reporting that regions of SPL are active both during shifts of attention in the visual periphery and when attention is focused on target stimuli but no attentional shifts are required²⁸. These findings fit well with neurological lesion studies finding that inferior regions of parietal cortex (extending into the temporoparietal junction) are more critical than superior parietal regions for normal performance in spatial cueing tasks²⁹.

Neuroimaging studies in humans reveal activations in the posterior STS during the performance of attentional tasks, suggesting that the STS may be involved in attentional processing in humans^{11,24}, a role supported by induction of attentional neglect in lesions of the STS in monkeys³⁰. However, it has remained unclear whether the STS is involved in attentional control circuitry, or instead is involved in attention-related processing of relevant target stimuli. We demonstrated that a region of the STS anterior to the temporal-parietal junction was selectively activated by the attention-directing cues, suggesting a role in attentional control circuitry.

The activations to the attention-directing cues in the vicinity of the frontal eye field in the present study suggest a role for this brain region in attentional control. The FEF is proposed to be involved in attentional processes, specifically as they relate to overt eye movements^{5,31}. Imaging studies, however, suggest that FEF may be involved in covert shifts of attention as well^{24,32}. In the present study,

the cortex in the vicinity of the FEF was activated by the cues, but not by the target stimuli, suggesting its participation in attentional-control processes in the absence of eye movements. Given that eye movements needed to be suppressed to both cue and target presentations, the present pattern cannot be attributed solely to suppression of oculomotor responses³³.

Regions of the dorsolateral prefrontal cortex (superior frontal gyrus) that were anterior to the FEF activations were also activated to the cues but not the targets. These regions of frontal cortex have been associated with working memory processes in studies of spatial working memory^{34–38}. In the present task, such processes may have activated these regions as subjects encoded the to-be-attended location in working memory.

In contrast, although ventrolateral prefrontal regions are sometimes considered to be involved in retention of information in working memory^{34,35}, in the present study, the strongest ventrolateral prefrontal activations were not observed in response to

the cue stimuli when one might expect working memory processes to be engaged. Rather, these cortical regions were activated upon presentation of the target stimuli. This finding may be consistent with a role in inhibitory filtering of information from the ignored hemifield when the bilateral targets appeared^{36–38}.

Previously, the supplementary motor area and the anterior cingulate cortex were hypothesized to be part of attentional control systems^{2,8}. The present finding that these areas were activated in response to the target stimuli but not the attention-directing cues, however, suggests a role in either the selective analysis of target features or decisional processes engaged once the relevant stimulus is presented, such as selecting appropriate motor actions based on target features^{39,40}.

As predicted by the previous literature, target-evoked activity in posterior lingual and fusiform regions was enhanced in the hemisphere contralateral to the direction of attention. This supports the idea that spatial attention-related increases in regional blood flow in extrastriate cortex are related to enhanced processing of target stimuli falling within the attentional spotlight, as suggested by prior ERP^{4,41,42} and functional imaging studies^{9,10,16–19} in humans and single-unit studies in monkeys^{3,43}. In addition, a more dorsal region of visual cortex was also enhanced by the direction of attention. This region may be area V3a, which has an upper visual field representation in dorsal visual cortex⁴⁴ and which is activated in response to flashing checkerboard patterns¹⁸.

Priming of visual neurons by top-down attentional control signals is suggested by the finding that regions of visual cortex

coding to-be-attended locations were differentially activated in response to the instruction to orient attention by the cue. Single-unit studies in non-human primates show an increase in background firing rates of neurons coding an attended region of space in the absence of stimuli⁴⁵, and proposals based on neuroimaging data suggest that increased background firing rates may mediate attentional facilitation in visual cortex^{46,47}. The present data show a precise spatial correspondence between areas of visual cortex activated by top-down processes and those showing subsequent selective modulations of target processing. Moreover, these priming effects in visual cortex were shown to follow the retinotopic mapping of the visual fields onto visual cortex as attention was shifted from left to right locations by the cue instructions.

In summary, a top-down attentional control system was isolated using event-related fMRI methods. This network included the superior frontal cortex, inferior parietal cortex, superior temporal cortex and portions of the posterior cingulate cortex and insula. The present evidence indicates that this top-down control system modulated activity in extrastriate cortex as a function of where spatial attention was directed in the visual field. These spatially selective effects in extrastriate cortex, observed before the presentation of the target stimuli, resulted in modulations in the activity evoked by subsequent target stimuli in precisely corresponding early cortical areas. Hence, it seems that effects of spatial attention in visual cortex before target onset may reflect changes in sensory-neural excitability as a function of top-down control. These findings provide direct evidence for clear distinctions between the neural mech-

anisms of attentional control and the resulting modulation of sensory signals. The challenge for the future is to relate activity in each of these identified brain regions to the specific neurocomputational operations they subservise during visual spatial attention.

METHODS

Stimuli and task parameters: cueing study. Each trial began with a cue that consisted of two overlapping isoluminant arrows presented at fixation (one blue and one yellow, pointing in opposite directions, each 1.9° tall \times 0.96° wide; duration, 500 ms). To eliminate differential activations based on the physical differences in right versus left cues, half the subjects were instructed to orient attention based on the direction of the blue arrow, and the other half were required to use the yellow arrow. The relevant arrow pointed randomly to the left or right. Target locations were demarcated by white outline rectangles (8.1° wide \times 7.2° tall, centered 5.6° above the horizontal meridian and 7.7° lateral to the vertical meridian) that remained on the screen throughout all runs.

Target stimuli appeared within the white outline rectangles and consisted of black and white checkerboards ($8.1^\circ \times 7.2^\circ$, composed of 0.9° square

checks) that reversed at 4 Hz over a 750-ms duration (so that each stimulus comprised 3 checkerboards lasting 250 ms each). A random one-half of target stimuli contained between 3 and 9 gray checks (randomly located) in place of white checks during one phase of the reversals (the second 250-ms period). Subjects were required to discriminate the target stimuli at the cued location only, pressing a button with one hand if gray checks were present, or pressing a button with the other hand if there were no gray checks (hand of response was counter-balanced across subjects). On 17% of trials, the target stimuli occurred 1000 ms after the offset of the cue. On the remaining 83% of trials, targets occurred 8160 ms following the cue. In order to distinguish the hemodynamic response to the cues from that to the targets, only the longer ISI data were analyzed and reported. The interval from the offset of the targets to the onset of the next trial cue was 7910 ms. Stimuli were delivered through an MRI-compatible goggle system (Resonance Technology, Northridge, California). Subjects were trained before the MRI session to ensure that the task was clearly understood and that subjects were able to perform the task without eye movements. In the scanner, they were instructed to covertly orient attention at the moment the cue was presented and to diligently maintain fixation throughout all runs; this was verified in control studies in two subjects using signal-averaged electrooculography outside the scanner. Speed of response was not emphasized, in order to minimize head-motion artifacts that might result from requiring a speeded response. Head motion was minimized by using a bite bar attached to the head coil. Six healthy adults (ages 22–34; 4 female) participated and gave written informed consent before all sessions. All procedures were approved by the UC Davis human subjects review committee. Each subject performed 5 runs of the task (396 s per run) while MRI data was acquired.

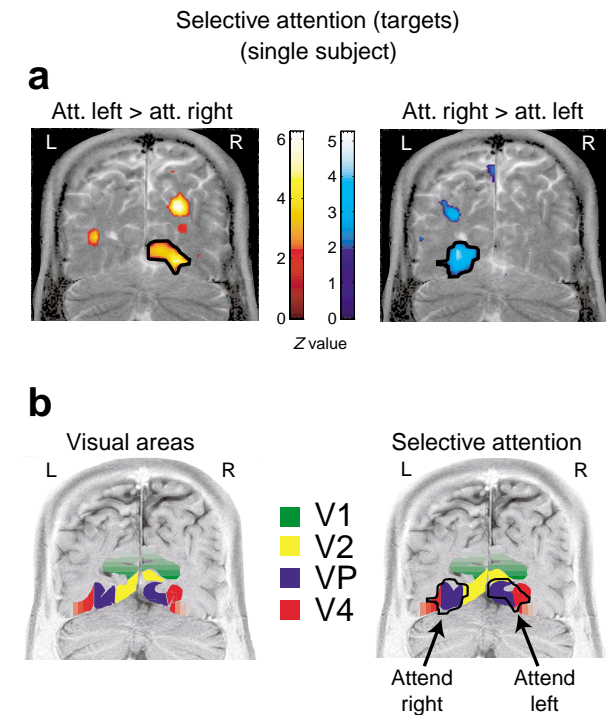

Stimuli and parameters: stimulation of meridia and control sessions. In two of the subjects, visual field mapping and cue control sessions were performed. Meridian stimuli for visual area mapping were $9.0^\circ \times 2.7^\circ$ checkerboard patterns aligned on the vertical or horizontal meridia and composed of alternating 0.9° square black and white checks, reversing at 15 Hz. Stimuli were presented in alternating 22-s blocks of right versus left meridia and in a separate run, upper versus lower meridia. The alternating pattern of vertical and horizontal meridia activations in visual cortex were used to identify the borders between V1, V2, VP and V4 (refs. 44, 47). For the cue sensory-control session, the cues used in the main experiment were flashed every 750 ms (duration, 500 ms) for 22 s alternating with 22-s no-stimulus blocks. A synthetic hemodynamic response function was convolved with the box-car function that represented the periodic alternation in the experimental conditions to yield the model response function that included a temporal derivative. Low-frequency drifts were modeled and filtered with a high-pass filter cutoff of 88 s, and the data were temporally smoothed by convolving the time series with a 4-s full width at half maximum (FWHM) Gaussian kernel. In another cue control, the cue and target stimuli were identical to that used in the main attention study except that the cues were not instructive as to where to orient attention. (Subjects had to

Fig. 5. Selective processing of target stimuli and retinotopy (single subject). (a) A T2-weighted coronal slice ($y = -72$) showing the activations due to selective visual attention on target processing for one subject. The left column shows the regions showing greater activity when attention was focused on the left visual field. The right column shows those areas showing greater activity when attention was focused on the right. Attention-related activations in the contralateral fusiform and lingual gyri are outlined in black (coordinates of left hemisphere maximum, $-32, -60, -8; Z = 5.26$; right hemisphere maximum, $20, -68, -8; Z = 5.39$). A more dorsal region in the cuneus (not outlined in black) also showed enhanced activity contralateral to the direction of attention (left hemisphere maximum = $-32, -64, 28, Z = 4.02$; right hemisphere maximum = $24, -72, 28, Z = 6.27$). (b) Left panel, ventral visual areas for the same subject shown at top, determined using the meridia scans (see Methods) and traced onto contrast-inverted, T2-weighted MRI scans ($y = -72$). Right panel, effect of attention to target stimuli on responses in lingual and fusiform gyri (shown as thick black outlines) overlaid onto the subject's retinotopically mapped visual areas. Attention-related target processing extends from V2 through V4 in the ventral visual-processing stream.

detect gray checks in both hemifields). During these sessions, target stimuli (250 ms) were presented on only 22% of trials with an ISI of 300 ms, whereas the other 78% of trials (catch trials) consisted only of the cue stimuli; only these catch trials were analyzed, using event-related methods (see below).

Scanning procedures. Functional images were acquired with a Signa Advantage 1.5 Tesla whole-body MRI system (General Electric, Waukesha, Wisconsin), with an elliptical end-capped quadrature radio frequency and local gradient head coil (Medical Advances, Milwaukee, Wisconsin). Images were acquired using T2*-weighted gradient-recalled echo, echo planar imaging (EPI) in the coronal plane with a repetition time (TR) of 2.75 seconds, an effective echo time (TE) of 40 ms and a flip angle (FA) of 90° . Twenty-two interleaved slices were collected with a 22-cm field of view (FOV), 64×64 matrix, slice thickness of 6 mm and an interslice gap of 2 mm, yielding a voxel size of $3.43 \times 3.43 \times 6.00$ mm³.

Fourier image reconstruction included N/2 ghost correction using image phase correction⁴⁸. Neural activation was detected via the blood oxygenation level dependent (BOLD) contrast mechanism¹⁵, which provided differences in signal intensity based upon differences in tissue T2* and perfusion. High-

resolution proton density and T2-weighted fast spin echo (FSE) images were also obtained in the coronal plane during the same scanning session. The anatomical scans were acquired with the following parameters: TR = 4.2 s; TE = 17 and 136 ms; echo train = 8; FOV = 22 cm, matrix = 512×256 (interpolated to 512×512 for display), slice thickness of 6 mm, with an interslice gap of 2 mm. In each EPI acquisition, 144 images were acquired at each of the 22 slice locations, for a total acquisition time of 396 s (6 min, 36 s).

Image processing. The first 16 images at each slice location (initial 44 s of acquisition) were discarded from the analysis. The remaining 128 images at each slice were used for the time-series analyses. Images were realigned and corrected for movement artifacts. The anatomical T2 images were coregistered with the proton density images and the functional images for each subject. Each subject's T2 (and coregistered proton density scans) were then

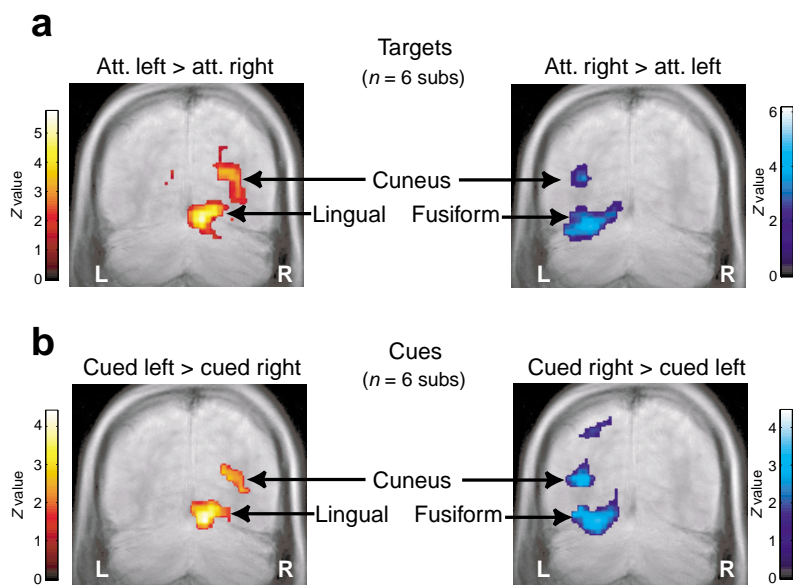

Fig. 6. Selective attention-related activations to targets and cues (group data). Results of group analysis showing regions with differential activity due to the direction of attention, overlaid onto averaged (6 subject) proton density MRI scans (slice at $y = -64$). (a) Target processing was enhanced in regions of visual cortex contralateral to the attended hemifield. These significant (all $p < 0.001$ corrected) attention-related activations were observed in the lingual and fusiform gyri in the right ($12, -64, -4; Z = 5.86$) and left ($-28, -60, -8; Z = 6.15$) hemispheres, and also in dorsal regions of the cuneus in the right ($24, -72, 28; Z = 6.04$) and left ($-28, -68, 24; Z = 5.30$) hemispheres. (b) Contralateral to the direction of attention, multiple regions of extrastriate cortex showed responses to the cue stimuli that differed based on the direction of attention, including the lingual and fusiform gyri ($12, -64, -4, Z = 4.51$; $-20, -64, -4, Z = 4.25$) as well as a more dorsal region of the cuneus ($24, -68, 28, Z = 3.87$; $-28, -68, 24, Z = 4.61$). The maxima of these activations were 0–1 cm from those in response to targets and were all significant at $p < 0.001$, uncorrected. (Because regions of interest analyzed for cue responses were specified *a priori* by analyses for attention effects on target responses, we give uncorrected p values for cue responses.)

spatially normalized to a standard stereotactic space⁴⁹ (using, however, the canonical Montreal Neurological Institute template in the SPM97 package), with the origin at the anterior commissure and the x - y plane extending through the anterior and posterior commissures. The functional images were then spatially normalized into stereotactic space, resampled to $4 \times 4 \times 4$ mm³ voxels and spatially smoothed with an 8-mm isotropic Gaussian kernel.

Event-related analyses. The responses of interest in the event-related design were modeled by convolving a vector containing the onset times of the cues and targets with a synthetic hemodynamic response function composed of the sum of two gamma functions and its temporal derivative (accounting for the hemodynamic response and subsequent undershoot and for slight variations in timing)⁵⁰. As a result, the present analysis emphasizes transient hemodynamic activity temporally adjacent to the cue and target events. Multiple linear regression (using a least-squares approach to estimate the parameters), as implemented in SPM97, was used to model the effects of interest and other confounding factors (such as session effects and low-frequency drifts of signal intensity) at every voxel simultaneously. Data from different sessions were proportionally scaled to a grand mean of 100 arbitrary units to account for overall differences in the intensity of whole brain volumes across the time series. Temporal smoothing was accomplished by convolving the data with a 4-s FWHM Gaussian filter (to account for temporal autocorrelations in the time series). An omnibus voxel-wise analysis provided an SPM(F), and those voxels with significant F -ratios ($p < 0.001$ uncorrected) were retained for further specific statistical tests. Specific hypotheses were then tested with t -tests at those voxels, and the resulting SPM(t) was transformed to the unit normal distribution resulting in the Z -scores and SPM(Z) maps in the figures and tables.

ACKNOWLEDGEMENTS

This research was supported by grants from the National Institute of Mental Health (MH55714 and MH57138) and Human Frontier Science Program to G.R.M., and a National Science Foundation fellowship to J.B.H. We thank Neva Corrigan for assistance in collecting the MRI data, Jeff Maxwell for assistance in collecting the EOG data, Karl Friston and Christian Buechel for advice regarding the event-related fMRI analyses and Kevin LaBar, Kevin Wilson, Barry Geisbrecht, Marty Woldorff, Daniel Weissman, Steven Hillyard and Tamara Swaab for comments on the manuscript.
